## Abstract

In regression, the desired estimate of  $y|x$  is not always given by a conditional mean, although this is most common. Sometimes one wants to obtain a good estimate that satisfies the property that a proportion,  $\tau$ , of  $y|x$ , will be below the estimate. For  $\tau = 0.5$  this is an estimate of the *median*. What might be called median regression, is subsumed under the term *quantile regression*. We present a nonparametric version of a quantile estimator, which can be obtained by solving a simple quadratic programming problem and provide uniform convergence statements and bounds on the quantile property of our estimator. Experimental results show the feasibility of the approach and competitiveness of our method with existing ones. We discuss several types of extensions including an approach to solve the *quantile crossing* problems, as well as a method to incorporate prior qualitative knowledge such as monotonicity constraints.

## 1. Introduction

Regression estimation is typically concerned with finding a real-valued function  $f$  such that its values  $f(x)$  correspond to the conditional mean of  $y$ , or closely related quantities. Many methods have been developed for this purpose, e.g. least mean square (LMS) regression (Vinod (1978)), robust regression (Huber (1981)), or  $\epsilon$ -insensitive regression (Vapnik (1995); Vapnik et al. (1997)). Regularized variants include Wahba (1990), penalized by a Reproducing Kernel Hilbert Space (RKHS) norm, and Hoerl and Kennard (1970), regularized via ridge regression.

### 1.1 Motivation

While these estimates of the mean serve their purpose, there exists a large area of problems where we are more interested in estimating a quantile. That is, we might wish to know other features of the the distribution of the random variable  $y|x$ :

- A device manufacturer may wish to know what are the 10% and 90% quantiles for some feature of the production process, so as to tailor the process to cover 80% of the devices produced.
- For risk management and regulatory reporting purposes, a bank may need to estimate a lower bound on the changes in the value of its portfolio which will hold with high probability.

- A pediatrician requires a growth chart for children given their age and perhaps even medical background, to help determine whether medical interventions are required, e.g. while monitoring the progress of a premature infant.

These problems are addressed by a technique called Quantile Regression (QR) championed by Koenker (see Koenker (2005) for a description, practical guide, and extensive list of references). These methods have been deployed in econometrics, social sciences, ecology, etc. The purpose of our paper is:

- To bring the technique of quantile regression to the attention of the machine learning community and show its relation to  $\nu$ -Support Vector Regression (Schölkopf et al. (2000)).
- To demonstrate a nonparametric version of QR which outperforms the currently available nonlinear QR regression formations (Koenker (2005)). See Section 5 for details.
- To derive small sample size results for the algorithms. Most statements in the statistical literature for QR methods are of asymptotic nature Koenker (2005). Empirical process results permit us to define two quality criteria and show tail bounds for both of them in the finite-sample-size case.
- To extend the technique to permit commonly desired constraints to be incorporated. As examples we show how to enforce non-crossing constraints and a monotonicity constraint. These constraints allow us to incorporate prior knowledge on the data.

## 1.2 Notation and Basic Definitions:

In the following we denote by  $\mathcal{X}, \mathcal{Y}$  the domains of  $x$  and  $y$  respectively.  $X = \{x_1, \dots, x_m\}$  denotes the training set with corresponding targets  $Y = \{y_1, \dots, y_m\}$ , both drawn independently and identically distributed (iid) from some distribution  $p(x, y)$ . With some abuse of notation  $y$  also denotes the vector of all  $y_i$  in matrix and vector expressions, whenever the distinction is obvious.

Unless specified otherwise  $\mathcal{H}$  denotes a Reproducing Kernel Hilbert Space (RKHS) on  $\mathcal{X}$ ,  $k$  is the corresponding kernel function, and  $K \in \mathbb{R}^{m \times m}$  is the kernel matrix obtained via  $K_{ij} = k(x_i, x_j)$ .  $\theta$  denotes a vector in *feature space* and  $\phi(x)$  is the corresponding feature map of  $x$ . That is,  $k(x, x') = \langle \phi(x), \phi(x') \rangle$ . Finally,  $\alpha \in \mathbb{R}^m$  is the vector of Lagrange multipliers.

**Definition 1 (Quantile)** *Denote by  $y \in \mathbb{R}$  a random variable and let  $\tau \in (0, 1)$ . Then the  $\tau$ -quantile of  $y$ , denoted by  $\mu_\tau$  is given by the infimum over  $\mu$  for which  $\Pr \{y \leq \mu\} = \tau$ . Likewise, the conditional quantile  $\mu_\tau(x)$  for a pair of random variables  $(x, y) \in \mathcal{X} \times \mathbb{R}$  is defined as the function  $\mu_\tau : \mathcal{X} \rightarrow \mathbb{R}$  for which pointwise  $\mu_\tau$  is the infimum over  $\mu$  for which  $\Pr \{y \leq \mu | x\} = \tau$ .*

## 1.3 Examples

To illustrate regression analyses with conditional quantile functions, we provide two simple examples here.

### 1.3.1 ARTIFICIAL DATA

The definition of conditional quantiles may be best illustrated by simple example. Consider a situation where  $x$  is drawn uniformly from  $[0, 1]$  and  $y$  is given by

$$y(x) = \sin \pi x + \xi \text{ where } \xi \sim \mathcal{N}(0, e^{\sin 2\pi x}).$$

Figure 1: Illustration of the nonparametric quantile regression on toy dataset. On the left,  $\tau = 0.9$ . On the right,  $\tau = 0.5$  the quantile regression line approximates the median of the data very closely (since  $\xi$  is normally distributed median and mean are identical).

Here the amount of noise is a function of the location. Since  $\xi$  is symmetric with mean and mode 0 we have  $\mu_{0.5}(x) = \sin \pi x$ . Moreover, we can compute the quantiles by solving for  $\Pr\{y \leq \mu|x\} = \tau$  explicitly.

Since  $\xi$  is normal we know that the quantiles of  $\xi$  are given by  $\Phi^{-1}(\tau) \sin 2\pi x$ , where  $\Phi$  is the cumulative distribution function of the normal distribution with unit variance. This means that

$$\mu_{\tau}(x) = \sin \pi x + \Phi^{-1}(\tau) \sin 2\pi x. \quad (1)$$

Figure 1 shows two quantile *estimates*. We see that depending on the choice of the quantile, we obtain a close approximation of the median ( $\tau = 0.5$ ), or a curve which tracks just inside the upper envelope of the data ( $\tau = 0.9$ ). The error bars of many regression estimates can be viewed as crude quantile regressions: one tries to specify the interval within which, with high probability, the data may lie. Note, however, that the latter does not entirely correspond to a quantile regression: error bars just give an upper bound on the range within which an estimate lies, whereas QR aims to estimate the exact boundary at which a certain quantile is achieved. In other words, it corresponds to tight error bars.

### 1.3.2 REAL DATA

The next example is based on actual measurements of bone density (BMD) in adolescents. The data was originally reported in Bachrach et al. (1999) and is also analyzed in Hastie et al. (2001)<sup>1</sup>. Figure 2 (a) shows a regression analysis with conditional mean and figure 2 (b) shows that with a set of conditional quantiles for the variable BMD.

The response in the vertical axis is relative change in spinal BMD and the covariate in the horizontal axis is the age of the adolescents. The conditional mean analysis (a) provides only the central tendency of the conditional distribution, while apparently the entire distribution of BMD changes according to age. The conditional quantile analysis (b) gives us more detailed description of these changes. For example, we can see that the variance of the BMD changes with the age (heteroscedastic) and that the conditional distribution is slightly positively skewed.

1. The data is also available from the website <http://www-stat.stanford.edu/ElemStatlearn>

Figure 2: An illustration of (a) conditional mean analysis and (b) conditional quantile analysis for a data set on bone mineral density (BMD) in adolescents. In (a) the conditional mean curve is estimated by regression spline with least square criterion. In (b) the nine curves are the estimated conditional quantile curves at orders  $0.1, 0.2, \dots, 0.9$ . The set of conditional quantile curves provides more informative description of the relationship among variables such as non-constant variance or non-normality of the noise (error) distribution. In this paper, we are concerned with the problem of estimating these conditional quantiles.

## 2. Quantile Regression

Given the definition of  $q_\tau(x)$  and knowledge of support vector machines we might be tempted to use version of the  $\epsilon$ -insensitive tube regression to estimate  $q_\tau(x)$ . More Specifically one might want to estimate quantiles nonparametrically using an extension of the  $\nu$ -trick, as outlined in Schölkopf et al. (2000). However this approach carries the disadvantage of requiring us to estimate both an upper and lower quantile *simultaneously*. While this can be achieved by quadratic programming, in doing so we estimate “too many” parameters simultaneously. More to the point, if we are interested in finding an upper bound on  $y$  which holds with 0.95 probability we may not want to use information about the 0.05 probability bound in the estimation. Following Vapnik’s paradigm of estimating only the relevant parameters directly Vapnik (1982) we attack the problem by estimating each quantile separately. For completeness and comparison, we provide a detailed description of a symmetric quantile regression in Appendix A.

### 2.1 Loss Function

The basic strategy behind quantile estimation arises from the observation that minimizing the  $\ell_1$ -loss function for a location estimator yields the median. Observe that to minimize  $\sum_{i=1}^m |y_i - \mu|$  by choice of  $\mu$ , an equal number of terms  $y_i - \mu$  have to lie on either side of zero in order for the derivative wrt.  $\mu$  to vanish. Koenker (2005) generalizes this idea to obtain a regression estimate for any quantile by tilting the loss function in a suitable fashion. More specifically one may show that the following “pinball” loss leads to estimates of the  $\tau$ -quantile:

$$l_\tau(\xi) = \begin{cases} \tau\xi & \text{if } \xi \geq 0 \\ (\tau - 1)\xi & \text{if } \xi < 0 \end{cases} \quad (2)$$

**Lemma 2 (Quantile Estimator)** Let  $Y = \{y_1, \dots, y_m\} \subset \mathbb{R}$  and let  $\tau \in (0, 1)$  then the minimizer  $\mu_\tau$  of  $\sum_{i=1}^m l_\tau(y_i - \mu)$  with respect to  $\mu$  satisfies:

1. The number of terms,  $m_-$ , with  $y_i < \mu_\tau$  is bounded from above by  $\tau m$ .
2. The number of terms,  $m_+$ , with  $y_i > \mu_\tau$  is bounded from above by  $(1 - \tau)m$ .
3. For  $m \rightarrow \infty$ , the fraction  $\frac{m_-}{m}$ , converges to  $\tau$  if  $\Pr(y)$  does not contain discrete components.

**Proof** Assume that we are at an optimal solution. Then, increasing the minimizer  $\mu$  by  $\delta\mu$  changes the objective by  $[(1 - m_+)(1 - \tau) - m_+\tau] \delta\mu$ . Likewise, decreasing the minimizer  $\mu$  by  $\delta\mu$  changes the objective by  $[-m_-(1 - \tau) + (1 - m_-)\tau] \delta\mu$ . Requiring that both terms are nonnegative at optimality in conjunction with the fact that  $m_- + m_+ \leq m$  proves the first two claims. To see the last claim, simply note that the event  $y_i = y_j$  for  $i \neq j$  has probability measure zero for distributions not containing discrete components. Taking the limit  $m \rightarrow \infty$  shows the claim. ■

The idea is to use the same loss function for functions,  $f(x)$ , rather than just constants in order to obtain quantile estimates conditional on  $x$ . Koencker Koenker (2005) uses this approach to obtain linear estimates and certain nonlinear spline models. In the following we will use kernels for the same purpose.

## 2.2 Optimization Problem

Based on  $l_\tau(\xi)$  we define the expected quantile risk as

$$R[f] := \mathbf{E}_{p(x,y)} [l_\tau(y - f(x))]. \quad (3)$$

By the same reasoning as in Lemma 2 it follows that for  $f : \mathcal{X} \rightarrow \mathbb{R}$  the minimizer of  $R[f]$  is the quantile  $\mu_\tau(x)$ . Since  $p(x, y)$  is unknown and we only have  $X, Y$  at our disposal we resort to minimizing the empirical risk plus a regularizer:

$$R_{\text{reg}}[f] := \frac{1}{m} \sum_{i=1}^m l_\tau(y_i - f(x_i)) + \frac{\lambda}{2} \|g\|_{\mathcal{H}}^2 \text{ where } f = g + b \text{ and } b \in \mathbb{R}. \quad (4)$$

Here  $\|\cdot\|_{\mathcal{H}}$  is RKHS norm and we require  $g \in \mathcal{H}$ . Notice that we do not regularize the constant offset,  $b$ , in the optimization problem. This ensures that the minimizer of (4) will satisfy the quantile property:

**Lemma 3 (Empirical Conditional Quantile Estimator)** Assuming that  $f$  contains a scalar unregularized term, the minimizer of (4) satisfies:

1. The number of terms  $m_-$  with  $y_i < f(x_i)$  is bounded from above by  $\tau m$ .

2. The number of terms  $m_+$  with  $y_i > f(x_i)$  is bounded from above by  $(1 - \tau)m$ .
3. If  $(x, y)$  is drawn iid from a distribution  $\Pr(x, y)$ , with  $\Pr(y|x)$  continuous and the expectation of the modulus of absolute continuity of its density satisfying  $\lim_{\delta \rightarrow 0} \mathbf{E}[\epsilon(\delta)] = 0$ . With probability 1, asymptotically,  $\frac{m_-}{m}$  equals  $\tau$ .

**Proof** For the two claims, denote by  $f^*$  the minimum of  $R_{\text{reg}}[f]$  with  $f^* = g^* + b^*$ . Then  $R_{\text{reg}}[g^* + b]$  has to be minimal for  $b = b^*$ . With respect to  $b$ , however, minimizing  $R_{\text{reg}}$  amounts to finding the  $\tau$  quantile in terms of  $y_i - g(x_i)$ . Application of Lemma 2 proves the first two parts of the claim.

For the second part, an analogous reasoning to (Schölkopf et al., 2000, Proposition 1) applies. In a nutshell, one uses the fact that the measure of the  $\delta$ -neighborhood of  $f(x)$  converges to 0 for  $\delta \rightarrow 0$ . Moreover, for kernel functions the entropy numbers are well behaved Williamson et al. (2001). The application of the union bound over a cover of such function classes completes the proof. Details are omitted, as the proof is identical to that in Schölkopf et al. (2000). ■

Later, in Section 4 we discuss finite sample size results regarding the convergence of  $\frac{m_-}{m} \rightarrow \tau$  and related quantities. These statements will make use of scale sensitive loss functions. Before we do that, let us consider the practical problem of minimizing the regularized risk functional.

### 2.3 Dual Optimization Problem

Here we compute the dual optimization problem to (4) for efficient numerical implementation. Using the connection between RKHS and feature spaces we write  $f(x) = \langle \phi(x), w \rangle + b$  and we obtain the following equivalent to minimizing  $R_{\text{reg}}[f]$ .

$$\underset{w, b, \xi_i^{(*)}}{\text{minimize}} \quad C \sum_{i=1}^m \tau \xi_i + (1 - \tau) \xi_i^* + \frac{1}{2} \|w\|^2 \quad (5a)$$

$$\text{subject to} \quad y_i - \langle \phi(x_i), w \rangle - b \leq \xi_i \text{ and } \langle \phi(x_i), w \rangle + b - y_i \leq \xi_i^* \text{ where } \xi_i, \xi_i^* \geq 0 \quad (5b)$$

Here we used  $C := 1/(\lambda m)$ . The dual of this problem can be computed straightforwardly using Lagrange multipliers. The dual constraints for  $\xi$  and  $\xi^*$  can be combined into one variable. This yields the following dual optimization problem

$$\underset{\alpha}{\text{minimize}} \quad \frac{1}{2} \alpha^\top K \alpha - \alpha^\top \vec{y} \quad \text{subject to} \quad C(\tau - 1) \leq \alpha_i \leq C\tau \text{ for all } 1 \leq i \leq m \text{ and } \vec{1}^\top \alpha = 0. \quad (6)$$

We recover the  $f$  via the familiar kernel expansion

$$w = \sum_i \alpha_i \phi(x_i) \text{ or equivalently } f(x) = \sum_i \alpha_i k(x_i, x) + b. \quad (7)$$

Note that the constant  $b$  is the dual variable to the constraint  $\vec{1}^\top \alpha = 0$ . Alternatively,  $b$  can be obtained by using the fact that  $f(x_i) = y_i$  for  $\alpha_i \notin \{C(\tau - 1), C\tau\}$ . The latter holds as a consequence of the KKT-conditions on the primal optimization problem of minimizing  $R_{\text{reg}}[f]$ .

Note that the optimization problem is very similar to that of an  $\epsilon$ -SV regression estimator Vapnik et al. (1997). The key difference between the two estimation problems is that in  $\epsilon$ -SVR we have an additional  $\epsilon \|\alpha\|_1$  penalty in the objective function. This ensures that observations with deviations from the estimate, i.e. with  $|y_i - f(x_i)| < \epsilon$  do not appear in the support vector expansion. Moreover the upper and lower

Figure 3: The data set measures acceleration in the head of a crash test dummy v. time in tests of motorcycle crashes. Three regularized versions of the median regression estimate ( $\tau = 0.5$ ). While all three variants satisfy the quantile property, the degree of smoothness is controlled by the regularization constant  $\lambda$ . All three estimates compare favorably to a similar graph of nonlinear QR estimates reported in Koenker (2005).

constraints on the Lagrange multipliers  $\alpha_i$  are matched. This means that we balance excess in both directions. The latter is useful for a regression estimator. In our case, however, we obtain an estimate which penalizes loss unevenly, depending on whether  $f(x)$  exceeds  $y$  or vice versa. This is exactly what we want from a quantile estimator: by this procedure errors in one direction have a larger influence than those in the converse direction, which leads to the shifted estimate we expect from QR.

The practical advantage of (6) is that it can be solved directly with standard quadratic programming code rather than using pivoting, as is needed in SVM regression Vapnik et al. (1997). Figure 3 shows how QR behaves subject to changing the model class, that is, subject to changing the regularization parameter. All three estimates in Figure 3 attempt to compute the median subject to different smoothness constraints. While they all satisfy the quantile property of having a fraction of  $\tau = 0.5$  points on either side of the regression, they track the observations more or less closely. Therefore a practical estimate requires a procedure for setting the regularization parameter. This question is taken up again in Section 5 where we compute quantile regression estimates on a range of datasets.

### 3. Extensions and Modifications

The mathematical programming framework lends itself naturally to a series of extensions and modifications of the regularized risk minimization framework for quantile regression. In the following we discuss some extensions and modifications.

#### 3.1 Non-crossing constraints

When we want to estimate several conditional quantiles (e.g.  $\tau = 0.1, 0.2, \dots, 0.9$ ), two or more estimated conditional quantile functions can cross or overlap. This embarrassing phenomenon called *quantile crossing* occurs because each conditional quantile function is independently estimated Koenker (2005); He (1997). Figure 4(a) shows BMD data presented in 1.3.2 and  $\tau = 0.1, 0.2, \dots, 0.9$  conditional quantile functions estimated by the kernel-based estimator described in the previous section. Both of the input and the output variables are standardized in  $[0, 1]$ . We note quantile crossings at several places, especially at the outside

of the training data range ( $x < 0$  and  $1 < x$ ). In this subsection, we address this problem by introducing *non-crossing constraints*. Figure 4(b) shows a family of conditional quantile functions estimated with the non-crossing constraints.

Suppose that we want to estimate  $n$  conditional quantiles at  $0 < \tau_1 < \tau_2 < \dots < \tau_n < 1$ . We enforce *non-crossing* constraints at  $l$  points  $\{x_j\}_{j=1}^l$  in the input domain  $\mathcal{X}$ . Let us write the model for the  $\tau_h$ -th conditional quantile function as  $f_h(x) = \langle \phi(x), w_h \rangle + b_h$  for  $h = 1, 2, \dots, n$ . In  $\mathcal{H}$  the non-crossing constraints are represented as linear constraints

$$\langle \phi(x_j), w_h \rangle + b_h \leq \langle \phi(x_j), w_{h+1} \rangle + b_{h+1}, \text{ for all } 1 \leq h \leq n-1, 1 \leq j \leq l. \quad (8)$$

Solving (5) or (6) for  $1 \leq h \leq n$  with non-crossing constraints (8) allows us to estimate  $n$  conditional quantile functions not crossing at  $l$  points  $x_1, \dots, x_l \in \mathcal{X}$ . The primal optimization problem is given by

$$\underset{w_h, b_h, \xi_{hi}^*}{\text{minimize}} \sum_{h=1}^n \left[ C \sum_{i=1}^m \tau_h \xi_{hi} + (1 - \tau_h) \xi_{hi}^* + \frac{1}{2} \|w_h\|^2 \right] \quad (9a)$$

$$\text{subject to } y_i - \langle \phi(x_i), w_h \rangle - b_h = \xi_{hi} - \xi_{hi}^* \text{ where } \xi_{hi}, \xi_{hi}^* \geq 0, \text{ for all } 1 \leq h \leq n, 1 \leq i \leq m. \quad (9b)$$

$$\{ \langle \phi(x_j), w_{h+1} \rangle + b_{h+1} \} - \{ \langle \phi(x_j), w_h \rangle + b_h \} \geq 0, \text{ for all } 1 \leq h \leq n-1, 1 \leq j \leq l. \quad (9c)$$

Using Lagrange multipliers, we can obtain the dual optimization problem:

$$\underset{\alpha_n, \theta_h}{\text{minimize}} \sum_{h=1}^n \left[ \frac{1}{2} \alpha_h^\top K \alpha_h + \alpha_h^\top \tilde{K} (\theta_{h-1} - \theta_h) + \frac{1}{2} (\theta_{h-1} - \theta_h)^\top \bar{K} (\theta_{h-1} - \theta_h) - \alpha_h^\top \vec{y} \right] \quad (10a)$$

$$\text{subject to } C(\tau_h - 1) \leq \alpha_{hi} \leq C\tau_h, \text{ for all } 1 \leq h \leq n, 1 \leq i \leq m, \quad (10b)$$

$$\theta_{hj} \geq 0, \text{ for all } 1 \leq h \leq n, 1 \leq j \leq l, \vec{1}^\top \alpha_h = 0, \text{ for all } 1 \leq h \leq n, \quad (10c)$$

where  $\theta_{hj}$  is the Lagrange multiplier of (9c) for all  $1 \leq h \leq n, 1 \leq j \leq l$ ,  $\tilde{K}$  is  $m \times l$  matrix with its  $(i, j)$ -th entry  $k(x_i, x_j)$ ,  $\bar{K}$  is  $l \times l$  matrix with its  $(j_1, j_2)$ -th entry  $k(x_{j_1}, x_{j_2})$  and  $\theta_h$  is  $l$ -vector with its  $j$ -th entry  $\theta_{hj}$  for all  $1 \leq h \leq n$ . For notational convenience we define  $\theta_{0j} = \theta_{nj} = 0$  for all  $1 \leq j \leq l$ . The model for conditional quantile  $\tau_h$ -th quantile function is now represented as

$$f_h(x) = \sum_{i=1}^m \alpha_{hi} k(x, x_i) + \sum_{j=1}^l (\theta_{h-1j} - \theta_{hj}) k(x, x_j) + b_h. \quad (11)$$

In section 5.2.1 we empirically investigate the effect of non-crossing constraints on the generalization performances.

### 3.2 Monotonicity and Growth Curves

Consider the situation of a health statistics office which wants to produce growth curves. That is, it wants to generate estimates of  $y$  being the height of a child given parameters  $x$  such as age, ethnic background, gender, parent's height, etc. Such curves can be used to assess whether a child's growth is abnormal.

A naive approach is to apply QR directly to the problem of estimating  $y|x$ . Note, however, that we have additional information about the biological process at hand: the height of every individual child is a *monotonically increasing* function of age. Without observing large amounts of data, there is no guarantee that the estimates  $f(x)$ , will also be monotonic functions of age.

Figure 4: An example of *quantile crossing* problem in BMD data set presented in Section 1. Both of the input and the output variable are standardized in  $[0, 1]$ . In (a) the set of conditional quantiles at  $0.1, 0.2, \dots, 0.9$  are estimated by the kernel-based estimator presented in the previous section. Quantile crossings are found at several points, especially at the outside of the training data range ( $x < 0$  and  $1 < x$ ). The plotted curves in (b) are the conditional quantile functions obtained with *non-crossing* constraints explained in Section 3.1. There are no *quantile crossing* even at the outside of the training data range.

To address this problem we adopt an approach similar to Vapnik et al. (1997); Smola and Schölkopf (1998) and impose constraints on the derivatives of  $f$  directly. While this only ensures that  $f$  is monotonic on the observed data  $X$ , we could always add more locations  $x'_i$  for the express purpose of enforcing monotonicity.

Formally, we require that for a differential operator  $D$ , such as  $D = \partial_{x_{\text{age}}}$  the estimate  $Df(x) \geq 0$  for all  $x \in X$ . Using the linearity of inner products we have

$$Df(x) = D(\langle \phi(x), w \rangle + b) = \langle D\phi(x), w \rangle = \langle \psi(x), w \rangle \text{ where } \psi(x) := D\phi(x). \quad (12)$$

Note that accordingly inner products between  $\psi$  and  $\phi$  can be obtained via  $\langle \psi(x), \phi(x') \rangle = D_1 k(x, x')$  and  $\langle \psi(x), \psi(x') \rangle = D_1 D_2 k(x, x')$ , where  $D_1$  and  $D_2$  denote the action of  $D$  on the first and second argument of  $k$  respectively. Consequently the optimization problem (5) acquires an additional set of constraints and we need to solve

$$\begin{aligned} & \underset{w, b, \xi_i}{\text{minimize}} \quad C \sum_{i=1}^m \tau \xi_i + (1 - \tau) \xi_i^* + \frac{1}{2} \|w\|^2 & (13) \\ & \text{subject to} \quad y_i - \langle \phi(x_i), w \rangle - b \leq \xi_i, \quad \langle \phi(x_i), w \rangle + b - y_i \leq \xi_i^* \text{ and } \langle \psi(x_i), w \rangle \geq 0 \text{ where } \xi_i, \xi_i^* \geq 0. \end{aligned}$$

Figure 5: Example plots from quantile regression with and without monotonicity constraints. The thin line represents the nonparametric quantile regression without monotonicity constraints whereas the thick line represents the nonparametric quantile regression with monotonicity constraints.

Since the additional constraint does not depend on  $b$  it is easy to see that the quantile property still holds. The dual optimization problem yields

$$\underset{\alpha, \beta}{\text{minimize}} \quad \frac{1}{2} \begin{bmatrix} \alpha \\ \beta \end{bmatrix}^\top \begin{bmatrix} K & D_1 K \\ D_2 K & D_1 D_2 K \end{bmatrix} \begin{bmatrix} \alpha \\ \beta \end{bmatrix} - \alpha^\top \vec{y} \quad (14a)$$

$$\text{subject to } C(\tau - 1) \leq \alpha_i \leq C\tau \text{ and } 0 \leq \beta_i \text{ for all } 1 \leq i \leq m \text{ and } \bar{1}^\top \alpha = 0. \quad (14b)$$

Here  $D_1 K$  is a shorthand for the matrix of entries  $D_1 k(x_i, x_j)$  and  $D_2 K, D_1 D_2 K$  are defined analogously. Here  $w = \sum_i \alpha_i \phi(x_i) + \beta_i \psi(x_i)$  or equivalently  $f(x) = \sum_i \alpha_i k(x_i, x) + \beta_i D_1 k(x_i, x) + b$ .

**Example** Assume that  $x \in \mathbb{R}^n$  and that  $x_1$  is the coordinate with respect to which we wish to enforce monotonicity. Moreover, assume that we use a Gaussian RBF kernel, that is

$$k(x, x') = \exp\left(-\frac{1}{2\sigma^2} \|x - x'\|^2\right). \quad (15)$$

In this case  $D_1 = \partial_1$  with respect to  $x$  and  $D_2 = \partial_1$  with respect to  $x'$ . Consequently we have

$$D_1 k(x, x') = \frac{x'_1 - x_1}{\sigma^2} k(x, x'); D_2 k(x, x') = \frac{x_1 - x'_1}{\sigma^2} k(x, x') \quad (16a)$$

$$D_1 D_2 k(x, x') = \left[ \sigma^{-2} - \frac{(x_1 - x'_1)^2}{\sigma^4} \right] k(x, x'). \quad (16b)$$

Plugging the values of (16) into (14) yields the quadratic program. Note also that both  $k(x, x')$  and  $D_1 k(x, x')$  ((16a)), are used in the function expansion.

If  $x_1$  were drawn from a discrete (yet ordered) domain we could replace  $D_1, D_2$  with a finite difference operator. This is still a linear operation on  $k$  and consequently the optimization problem remains unchanged besides a different functional form for  $D_1 k$ .

### 3.3 Other Function Classes

**Semiparametric Estimates** RKHS expansions may not be the only function classes desired for quantile regression. For instance, in the social sciences a semiparametric model may be more desirable, as it allows for interpretation of the linear coefficients (Gu and Wahba (1993); Smola et al. (1999); Bickel et al. (1994)). In this case we add a set of parametric functions  $f_i$  and solve

$$\text{minimize } \frac{1}{m} \sum_{i=1}^m l_\tau(y_i - f(x_i)) + \frac{\lambda}{2} \|g\|_{\mathcal{H}_C}^2 \text{ where } f(x) = g(x) + \sum_{i=1}^n \beta_i f_i(x) + b. \quad (17)$$

For instance, the function class  $f_i$  could be linear coordinate functions, that is,  $f_i(x) = x_i$ . The main difference to (6) is that the resulting optimization problem exhibits a larger number of equality constraint. We obtain (6) with the additional constraints

$$\sum_{j=1}^m \alpha_j f_i(x_j) = 0 \text{ for all } i. \quad (18)$$

**Linear Programming Regularization** Convex function classes with  $\ell_1$  penalties can be obtained by imposing an  $\|\alpha\|_1$  penalty instead of the  $\|g\|_{\mathcal{H}_C}^2$  penalty in the optimization problem. The advantage of this setting is that minimizing

$$\text{minimize } \frac{1}{m} \sum_{i=1}^m l_\tau(y_i - f(x_i)) + \lambda \sum_{j=1}^n |\alpha_j| \text{ where } f(x) = \sum_{i=1}^n \alpha_i f_i(x) + b. \quad (19)$$

is a *linear program* which can be solved efficiently by existing codes for large scale problems. In the context of (19) the functions  $f_i$  constitute the generators of the convex function class. This approach is similar to Koenker and Park (1996) and Bosch et al. (1995). The former discuss  $\ell_1$  regularization of expansion coefficients whereas the latter discuss an explicit second order smoothing spline method for the purpose of quantile regression. Most of the discussion in the present paper can be adapted to this case without much modification. For details on how to achieve this see Schölkopf and Smola (2002). Note that smoothing splines are a special instance of kernel expansions where one assumes explicit knowledge of the basis functions.

**Relevance Vector Regularization and Sparse Coding** Finally, for sparse expansions one can use more aggressive penalties on linear function expansions than those given in (19). For instance, we could use a staged regularization as in the RVM (Tipping (2001)), where a quadratic penalty on each coefficient is exerted with a secondary regularization on the penalty itself. This corresponds to a Student-t penalty on  $\alpha$ .

Likewise we could use a mix between an  $\ell_1$  and  $\ell_0$  regularizer as used in Fung et al. (2002) and apply successive linear approximation. In short, there exists a large number of regularizers, and (non)parametric families which can be used. In this sense the RKHS parameterization is but one possible choice. Even so, we show in Section 5 that QR using the RKHS penalty yields excellent performance in experiments.

## 4. Theoretical Analysis

### 4.1 Performance Indicators

In this section we state some performance bounds for our estimator. For this purpose we first need to discuss how to evaluate the performance of the estimate  $f$  versus the true conditional quantile  $\mu_\tau(x)$ . Two criteria are important for a good quantile estimator  $f_\tau$ :

- $f_\tau$  needs to satisfy the quantile property as well as possible. That is, we want that

$$\Pr_{X,Y} \{ |\Pr \{y < f_\tau(x)\} - \tau| \geq \epsilon \} \leq \delta. \tag{20}$$

In other words, we want that the probability that  $y < f_\tau(x)$  does not deviate from  $\tau$  by more than  $\epsilon$  with high probability, when viewed over all draws  $(X, Y)$  of training data. Note however, that (20) does not imply having a conditional quantile estimator at all. For instance, the constant function based on the unconditional quantile estimator with respect to  $Y$  performs extremely well under this criterion. Hence we need a second quantity to assess how closely  $f_\tau(x)$  tracks  $\mu_\tau(x)$ .

- Since  $\mu_\tau$  itself is not available, we take recourse to (3) and the fact that  $\mu_\tau$  is the minimizer of the expected risk  $R[f]$ . While this will not allow us to compare  $\mu_\tau$  and  $f_\tau$  directly, we can at least compare it by assessing how close to the minimum  $R[f_\tau^*]$  the estimate  $R[f_\tau]$  is. Here  $f_\tau^*$  is the minimizer of  $R[f]$  with respect to the chosen function class. Hence we will strive to bound

$$\Pr_{X,Y} \{ R[f_\tau] - R[f_\tau^*] > \epsilon \} \leq \delta. \tag{21}$$

These statements will be given in terms of the Rademacher complexity of the function class of the estimator as well as some properties of the loss function used in select it. The technique itself is standard and we believe that the bounds can be tightened considerably by the use of *localized* Rademacher averages Mendelson (2003), or similar tools for empirical processes. However, for the sake of simplicity, we use the tools from Bartlett and Mendelson (2002), as the key point of the derivation is to describe a new setting rather than a new technique.

### 4.2 Bounding $R[f_\tau^*]$

**Definition 4 (Rademacher Complexity)** Let  $X := \{x_1, \dots, x_m\}$  be drawn iid from  $p(x)$  and let  $\mathcal{F}$  be a class of functions mapping from  $(X)$  to  $\mathbb{R}$ . Let  $\sigma_i$  be independent uniform  $\{\pm 1\}$ -valued random variables. Then the Rademacher complexity  $R_m$  and its empirical variant  $\hat{R}_m$  are defined as follows:

$$\hat{R}_m(\mathcal{F}) := \mathbf{E}_\sigma \left[ \sup_{f \in \mathcal{F}} \left| \frac{2}{m} \sum_1^n \sigma_i f(x_i) \right| \mid X \right] \text{ and } R_m(\mathcal{F}) := \mathbf{E}_X \left[ \hat{R}_m(\mathcal{F}) \right]. \tag{22}$$

Conveniently, if  $\Phi$  is a Lipschitz continuous function with Lipschitz constant  $L$ , one can show Bartlett and Mendelson (2002) that

$$R_m(\Phi \circ \mathcal{F}) \leq 2LR_m(\mathcal{F}) \text{ where } \Phi \circ \mathcal{F} := \{g|g = \phi \circ f \text{ and } f \in \mathcal{F}\}. \quad (23)$$

An analogous result exists for empirical quantities bounding  $\hat{R}_m(\Phi \circ \mathcal{F}) \leq 2L\hat{R}_m(\mathcal{F})$ . The combination of (23) with (Bartlett and Mendelson, 2002, Theorem 8) yields:

**Theorem 5 (Concentration for Lipschitz Continuous Functions)** *For any Lipschitz continuous function  $\Phi$  with Lipschitz constant  $L$  and a function class  $\mathcal{F}$  of real-valued functions on  $\mathcal{X}$  and probability measure on  $\mathcal{X}$  the following bound holds with probability  $1 - \delta$  for all draws of  $X$  from  $\mathcal{X}$ :*

$$\sup_{f \in \mathcal{F}} \left| \mathbf{E}_x [\Phi(f(x))] - \frac{1}{m} \sum_{i=1}^m \Phi(f(x_i)) \right| \leq 2LR_m(\mathcal{F}) + \sqrt{\frac{8 \log 2/\delta}{m}}. \quad (24)$$

We can immediately specialize the theorem to the following statement about the loss for QR:

**Theorem 6** *Denote by  $f_\tau^*$  the minimizer of the  $R[f]$  with respect to  $f \in \mathcal{F}$ . Moreover assume that all  $f \in \mathcal{F}$  are uniformly bounded by some constant  $B$ . With the conditions listed above for any sample size  $m$  and  $0 < \delta < 1$ , every quantile regression estimate  $f_\tau$  satisfies with probability at least  $(1 - \delta)$*

$$R[f_\tau] - R[f_\tau^*] \leq 2 \max L R_m(\mathcal{F}) + (4 + LB) \sqrt{\frac{\log 2/\delta}{2m}} \text{ where } L = \{\tau, 1 - \tau\}. \quad (25)$$

**Proof** We use the standard bounding trick that

$$R[f_\tau] - R[f_\tau^*] \leq |R[f_\tau] - R_{\text{emp}}[f_\tau]| + R_{\text{emp}}[f_\tau^*] - R[f_\tau^*] \quad (26)$$

$$\leq \sup_{f \in \mathcal{F}} |R[f] - R_{\text{emp}}[f]| + R_{\text{emp}}[f_\tau^*] - R[f_\tau^*] \quad (27)$$

where (26) follows from  $R_{\text{emp}}[f_\tau] \leq R_{\text{emp}}[f_\tau^*]$ . The first term can be bounded directly by Theorem 5. For the second part we use Hoeffding's bound Hoeffding (1963) which states that the deviation between a bounded random variable and its expectation is bounded by  $B\sqrt{\frac{\log 1/\delta}{2m}}$  with probability  $\delta$ . Applying a union bound argument for the two terms with probabilities  $2\delta/3$  and  $\delta/3$  yields the confidence-dependent term. Finally, using the fact that  $l_\tau$  is Lipschitz continuous with  $L = \max(\tau, 1 - \tau)$  completes the proof. ■

**Example** Assume that  $\mathcal{H}$  is an RKHS with radial basis function kernel  $k$  for which  $k(x, x) = 1$ . Moreover assume that for all  $f \in \mathcal{F}$  we have  $\|f\|_{\mathcal{H}} \leq C$ . In this case it follows from Mendelson (2003) that  $R_m(\mathcal{F}) \leq \frac{2C}{\sqrt{m}}$ . This means that the bounds of Theorem 6 translate into a rate of convergence of

$$R[f_\tau] - R[f_\tau^*] = O(m^{-\frac{1}{2}}). \quad (28)$$

This is as good as it gets for nonlocalized estimates. Since we do not expect  $R[f]$  to vanish except for pathological applications where quantile regression is inappropriate (that is, cases where we have a deterministic dependency between  $y$  and  $x$ ), the use of localized estimates Bartlett et al. (2002) provides only limited returns. We believe, however, that the constants in the bounds could benefit from considerable improvement.

Figure 6: Ramp functions bracketing the characteristic function via  $r_\epsilon^+ \geq \chi_{(-\infty, 0]} \geq r_\epsilon^-$ .

### 4.3 Bounds on the Quantile Property

The theorem of the previous section gave us some idea about how far the sample average quantile loss is from its true value under  $p$ . We now proceed to stating bounds to which degree  $f_\tau$  satisfies the quantile property, i.e. (20).

In this view (20) is concerned with the deviation  $\mathbf{E} [\chi_{(-\infty, 0]}(y - f_\tau(x))] - \tau$ . Unfortunately  $\chi_{(-\infty, 0]} \circ \mathcal{F}$  is not scale dependent. In other words, small changes in  $f_\tau(x)$  around the point  $y = f_\tau(x)$  can have large impact on (20). One solution for this problem is to use an artificial margin  $\epsilon$  and ramp functions  $r_\epsilon^+, r_\epsilon^-$  as defined in Figure 6. These functions are Lipschitz continuous with constant  $L = 1/\epsilon$ . This leads to:

**Theorem 7** *Under the assumptions of Theorem 6 the expected quantile is bounded with probability  $1 - \delta$  each from above and below by*

$$\frac{1}{m} \sum_{i=1}^m r_\epsilon^-(y_i - f(x_i)) - \Delta \leq \mathbf{E} [\chi_{(-\infty, 0]}(y - f_\tau(x))] \leq \frac{1}{m} \sum_{i=1}^m r_\epsilon^+(y_i - f(x_i)) + \Delta, \quad (30)$$

where the statistical confidence term is given by  $\Delta = \frac{2}{\epsilon} R_m(\mathcal{F}) + \sqrt{\frac{-8 \log \delta}{m}}$ .

**Proof** The claim follows directly from Theorem 5 and the Lipschitz continuity of  $r_\epsilon^+$  and  $r_\epsilon^-$ . Note that  $r_\epsilon^+$  and  $r_\epsilon^-$  minorize and majorize  $\chi_{(-\infty, 0]}$ , which bounds the expectations. Next use a Rademacher bound on the class of loss functions induced by  $r_\epsilon^+ \circ \mathcal{F}$  and  $r_\epsilon^- \circ \mathcal{F}$  and note that the ramp loss has Lipschitz constant  $L = 1/\epsilon$ . Finally apply the union bound on upper and lower deviations. ■

Note that Theorem 7 allows for some flexibility: we can decide to use a very conservative bound in terms of  $\epsilon$ , i.e. a large value of  $\epsilon$  to reap the benefits of having a ramp function with small  $L$ . This leads to a lower bound on the Rademacher average of the induced function class. Likewise, a small  $\epsilon$  amounts to a potentially tight approximation of the empirical quantile, while risking loose statistical confidence terms.

## 5. Experiments

### 5.1 Experiments with standard nonparametric quantile regression

The present section mirrors the theoretical analysis of the previous section. We check the performance of various quantile estimators with respect to two criteria:

- Expected risk with respect to the  $\ell_\tau$  loss function. Since computing the true conditional quantile is impossible and all approximations of the latter rely on intermediate density estimation Koenker (2005) this is the only objective criterion we could find.

- Simultaneously we need to ensure that the estimate satisfies the quantile property, that is, we want to ensure that the estimator we obtained does indeed produce numbers  $f_\tau(x)$  which exceed  $y$  with probability close to  $\tau$ .

### 5.1.1 MODELS

We compare the following four models:

- An unconditional quantile estimator. Given the simplicity of the function class (constants!) this model should tend to underperform all other estimates in terms of minimizing the empirical risk. By the same token, it should perform best in terms of preserving the quantile property.
- Linear QR as described in Koenker (2005). This uses the a linear unregularized model to minimize  $l_\tau$ . In experiments, we used the `rq` routine available in the  $R^2$  package called `quantreg`.
- Nonparametric QR as described by Koenker (2005) (Ch. 7). This uses a spline model for each coordinate individually, with linear effect. The fitting routine used was `rqss`, also available in `quantreg`.<sup>3</sup>
- Nonparametric quantile regression as described in Section 2. We used Gaussian RBF kernels with automatic kernel width ( $\omega^2$ ) and regularization ( $C$ ) adjustment by 10-fold cross-validation. This appears as `nprq`.<sup>4</sup>

As we increase the complexity of the function class (from constant to linear to nonparametric) we expect that (subject to good capacity control) the expected risk will decrease. Simultaneously we expect that the quantile property becomes less and less maintained, as the function class grows. This is exactly what one would expect from Theorems 6 and 7. As the experiments show, the `nprq` method outperforms all other estimators significantly in most cases. Moreover, it compares favorably in terms of preserving the quantile property.

### 5.1.2 DATASETS

We chose 20 regression datasets from the following R packages: `mlbench`, `quantreg`, `alr3` and `MASS`. The first library contains datasets from the UCI repository. The last two were made available as illustrations for regression textbooks. The data sets are all documented and available in  $R$ . Data sets were chosen not to have any missing variables, to have suitable datatypes, and to be of a size where all models would run on them.<sup>5</sup> In most cases either there was an obvious variable of interest, which was selected as the  $y$ -variable, or else we chose a continuous variable arbitrarily. The sample sizes vary from  $m = 38$  (CobarOre) to  $m = 1375$  (heights), and the number of regressors vary from  $d = 1$  (5 sets) and  $d = 12$  (BostonHousing). Some of the data sets contain categorical variables. We omitted variables which were effectively record identifiers, or obviously produced very small groupings of records. Finally, we *standardized* all datasets coordinatwise to have zero mean and unit variance before running the algorithms. This had a side benefit of putting the pinball loss on similar scale for comparison purposes.

2. See <http://cran.r-project.org/>

3. Additional code containing bugfixes and other operations necessary to carry out our experiments is available at <http://users.rsise.anu.edu.au/~timsears>.

4. Code will be available as part of the CREST toolbox for research purposes.

5. The last requirement, using `rqss` proved to be challenging. The underlying spline routines do not allow extrapolation beyond the previously seen range of a coordinate, only permitting interpolation. This does not prevent fitting, but does randomly prevent forecasting on unseen examples, which was part of our performance metric.

Data Set	Sample Size	No. Regressors (x)	Y Var.	Dropped Vars.

### 5.1.3 RESULTS

We tested the performance of the 4 algorithms on 3 different quantiles ( $\tau \in \{0.1, 0.5, 0.9\}$ ). For each model we used 10-fold cross-validation to assess the confidence of our results. For the `npqr` model, kernel width and smoothness parameters were automatically chosen by cross-validation within the training sample. We performed 10 runs on the training set to adjust parameters, then chose the best parameter setting based on the pinball loss averaged over 10 splits. To compare across all four models we measured both pinball loss and quantile performance.

The full results are shown in Appendix B. The 20 data sets and three quantile levels yield 60 trials for each model. In terms of pinball loss averaged across 10 tests the `npqr` model performed best or tied on 51 of the 60 trials, showing the clear advantage of the proposed method. The results are consistent across quantile levels. We can get another impression of performance by looking at the loss in each of the 10 test runs that enter each trial. This is depicted in Figure 5.1.3. In a large majority of test cases the `npqr` model error is smaller than that of the other models, resulting in a “cloud” centered below the 45 degree line.

Moreover, the quantile properties of all four methods are comparable. All four models produced ramp losses close to the desired quantile, although the `rqs` and `npqr` models were noisier in this regard. The complete results for the ramp loss are presented in last three tables in Appendix B. A slight downward bias seen in all models is reviewed in the Discussion.

## 5.2 Experiments on nonparametric quantile regression with additional constraints

We empirically investigate the performances of nonparametric quantile regression estimator with the additional constraints described in section 3. Imposing constraints is one way to introduce the prior knowledge on the data set being analyzed. Although additional constraints always increase training errors, we will see that these constraints can sometimes reduce test errors.

### 5.2.1 NON-CROSSING CONSTRAINTS

First we look at the effect of non-crossing constraints on the generalization performances. We used the same 20 data sets mentioned in the previous subsection using only the `npqr` model. We denote the `npqr`s trained with non-crossing constraints as `noncross` and `npqr` indicates standard one here. We made comparisons between `npqr` and `noncross` with  $\tau \in \{0.1, 0.5, 0.9\}$ . The results for `noncross` with  $\tau = 0.1$  were obtained by training a pair of non-crossing models with  $\tau = 0.1$  and 0.2. The results with  $\tau = 0.5$  were obtained by training three non-crossing models with  $\tau = 0.4, 0.5$  and 0.6. The results with  $\tau = 0.9$  were obtained by training a pair of non-crossing models with  $\tau = 0.8$  and 0.9. In this experiment, we simply impose non-crossing constraints only at a single test point to be evaluated. The kernel width and smoothing parameter were always set to be the selected ones in the above standard `npqr` experiments. The confidences were assessed by 10-fold cross-validation in the same way as the previous section. The complete results are found in the tables in Appendix B. The performances of `npqr` and `noncross` are quite similar since `npqr` itself could produce *almost* non-crossing estimates and the constraints only make a *small* adjustments only when there happen to be the violations.

### 5.2.2 MONOTONICITY CONSTRAINTS

We compare two models:

- Nonparametric QR as described in Section 2 (`npqr`).
- Nonparametric QR with monotonicity constraints as described in Section 3.2 (`npqrm`).

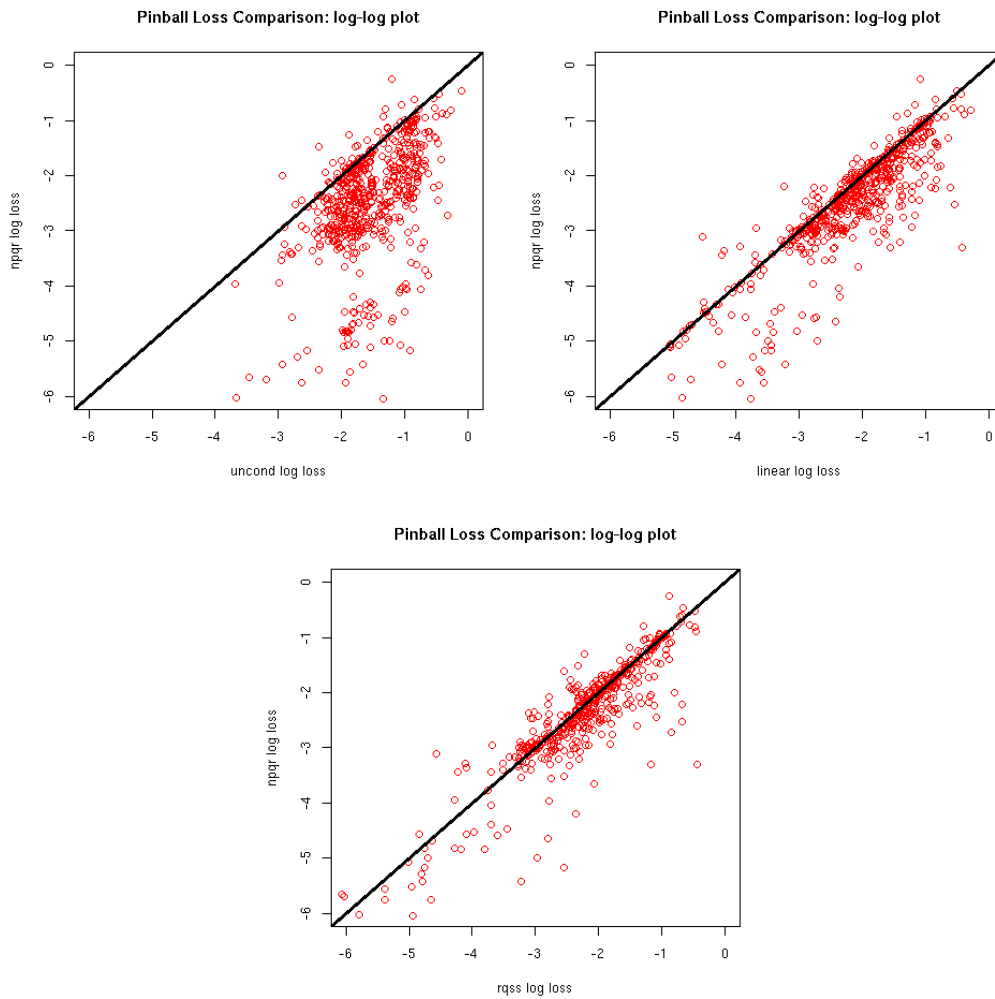

Figure 7: A log-log plot of out-of-sample performance obtained from the cross validation runs. The plots show npqr versus uncond, linear, and rqss; combining the values from all three estimated quantiles. Each point *below* the 45-degree line represents a case where the npqr achieves a better loss than the alternative and vice versa. The location of the cloud provides an impression of the relative generalization performance of each pair of models.

We use two datasets:

- The *cars* dataset as described in Mammen et al. (2001). Fuel efficiency (in miles per gallon) is studied as a function of engine output.

- The *onions* dataset as described in Ruppert and Carroll (2003).  $\log(\text{Yield})$  is studied as a function of density, we use only the measurements taken at Purnong Landing.

We tested the performance of the two methods on 3 different quantiles ( $\tau \in \{0.1, 0.5, 0.9\}$ ). In the experiments with *cars*, we noticed that the data is not truly monotonic. Monotonic models (*npqrm*) tend to do worse than standard models (*npqr*) for lower quantiles. With higher quantiles, *npqrm* tends to do better than the standard *npqr*.

For the *onions* dataset, as the data is truly monotonic the *npqrm* does better than the standard *npqr* in terms of the pinball loss.

## 6. Discussion and Extensions

Frequently in the literature of regression, including quantile regression, we encounter the term “exploratory data analysis”. This is meant to describe a phase before the user has settled on a “model”, after which some statistical tests are performed, justifying the choice of the model. Quantile regression, which allows the user to highlight many aspects of the distribution, is indeed a useful tool for this type of analysis. We also note that no attempts at statistical modeling beyond automatic parameter choice via cross-validation, were made to tune the results. So the effort here stays true to that spirit, yet may provide useful estimates immediately.

In the Machine Learning literature the emphasis is more on short circuiting many aspects of the modeling process. While not truly model-free, the experience of comparing the models in this paper shows how easy it is to estimate the quantities of interest in QR, without any of the angst of model selection. It is interesting to consider whether kernel methods, with proper regularization, are a good substitute for some traditional modeling activity. In particular we were able to some simpler traditional statistical estimates significantly, which allows the human modeler to focus on statistical concerns at a higher level.

In summary, we have presented a Quadratic Programming method for estimating quantiles which bests the state of the art in statistics. It is easy to implement, we provided uniform convergence results and experimental evidence for its soundness. We also introduce non-crossing and monotonicity constraints as extensions to avoid embarrassing behaviours of the model when doing quantile regression.

**Overly Optimistic Estimates for Ramp Loss** The experiments show us that there is a bias towards the median in terms of the ramp loss. For example, if we run a quantile estimator for at 0.05, then we will not necessarily get the empirical quantile is also at 0.05 but more likely to be at 0.08 or higher. Likewise, the empirical quantile will be 0.93 or lower if the estimator is run at 0.9. This affects all estimators, using the pinball loss as the loss function, not just the kernel version.

This is because the algorithm tends to aggressively push a number of points to the kink in the training set, these points will then be miscounted. However, in the testing set it is very unlikely to get the points lying exactly at the kink. Figure 8 shows us there is a linear relationship between the fraction of points at and below the kink (for low quantiles) and below the kink (for higher quantiles) with the empirical ramp loss.

Accordingly, to get a better performance in terms of the ramp loss, we just estimate the quantiles, and if they turn out to be too optimistic on the training set, we use a slightly lower (for  $\tau < 0.5$ ) or higher (for  $\tau > 0.5$ ) value of  $\tau$  until we have exactly the right quantity.

The fact that there is a number of points sitting exactly on the kink (quantile regression - this paper), the edge of the tube ( $\nu$ -SVR - see Schölkopf et al. (2000)), or the supporting hyperplane (single-class problems and novelty detection - see Schölkopf et al. (1999)) might affect the overall accuracy control in the test set has not been carefully studied so far thus needs more attention from the community.

Figure 8: Illustration of the relationship between quantile in training and ramp loss.

**Estimation with constraints** We introduce non-crossing and monotonicity constraints in the context of nonparametric quantile regression. However, as discussed in Mammen et al. (2001), other constraints can also be applied very similarly to the constraints described in this paper but might be in different estimation contexts. Here are some variations:

- *Boundary conditions.* The regression function is defined in  $[a, b]$  and assumed to be  $v$  at the boundary point  $a$  or  $b$ .
- *Additive models with monotone components.* The regression function  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  is of additive form  $f(x_1, \dots, x_n) = f_1(x_1) + \dots + f_n(x_n)$  where each additive component  $f_i$  is monotonic.
- *Observed derivatives.* Assume that  $m$  samples are observed corresponding with  $m$  regression functions. Now, the constraint is that  $f_j$  coincides with the derivative of  $f_{j-1}$  (same notation with last point) Cox (1988).
- *Bivariate extreme-value distributions.* See Hall and Tajvidi (2000).
- *Positivity constraints.* The regression function is positive.

**Future Work** Quantile regression has been mainly used as a data analysis tool to assess the influence of individual variables. This is an area where we expect that nonparametric estimates will lead to better performance.

Being able to estimate an upper bound on a random variable  $y|x$  which hold with probability  $\tau$  is useful when it comes to determining the so-called Value at Risk of a portfolio. Note, however, that in this situation we want to be able to estimate the regression quantile for a large set of different portfolios. For example, an investor may try to optimize their portfolio allocation to maximize return while keeping risk within a constant bound. Such uniform statements will need further analysis if we are to perform nonparametric estimates. We need more efficient optimization algorithm for non-crossing constraints since we have to work with  $O(nm)$  dual variables. Simple SVM Vishwanathan et al. (2003) would be the promising candidate for this purpose.

## Appendix A. Nonparametric $\nu$ -Support Vector Regression

In this section we explore an alternative to the quantile regression framework proposed in Section 2. It derives from Schölkopf et al. (2000). There the authors suggest a method for adapting SV regression and classification estimates such that automatically only a quantile  $\nu$  lies beyond the desired confidence region. In particular, if  $p(y|x)$  can be modeled by additive noise of equal degree (i.e.  $y = f(x) + \xi$  where  $\xi$  is a random variable independent of  $x$ ) Schölkopf et al. (2000) show that the  $\nu$ -SV regression estimate does converge to a quantile estimate.

### A.1 Heteroscedastic Regression

Whenever the above assumption on  $p(y|x)$  is violated  $\nu$ -SVR will not perform as desired. This problem can be amended as follows: one needs to turn  $\epsilon(x)$  into a nonparametric estimate itself. This means that we solve the following optimization problem.

$$\underset{\theta_1, \theta_2, b, \epsilon}{\text{minimize}} \quad \frac{\lambda_1}{2} \|\theta_1\|^2 + \frac{\lambda_2}{2} \|\theta_2\|^2 + \sum_{i=1}^m (\xi_i + \xi_i^*) - \nu m \epsilon \quad (31a)$$

$$\text{subject to} \quad \langle \phi_1(x_i), \theta_1 \rangle + b - y_i \leq \epsilon + \langle \phi_2(x_i), \theta_2 \rangle + \xi_i \quad (31b)$$

$$y_i - \langle \phi_1(x_i), \theta_1 \rangle - b \leq \epsilon + \langle \phi_2(x_i), \theta_2 \rangle + \xi_i^* \quad (31c)$$

$$\xi_i, \xi_i^* \geq 0 \quad (31d)$$

Here  $\phi_1, \phi_2$  are feature maps,  $\theta_1, \theta_2$  are corresponding parameters,  $\xi_i, \xi_i^*$  are slack variables and  $b, \epsilon$  are scalars. The key difference to the heteroscedastic estimation problem described in Schölkopf et al. (2000) is that in the latter the authors assume that the specific form of the noise is *known*. In (31) instead, we make no such assumption and instead we estimate  $\epsilon(x)$  as  $\langle \phi_2(x), \theta_2 \rangle + \epsilon$ .

By Lagrange multiplier methods one may check that the dual of (31) is obtained by

$$\underset{\alpha, \alpha^*}{\text{minimize}} \quad \frac{1}{2\lambda_1} (\alpha - \alpha^*)^\top K_1 (\alpha - \alpha^*) + \frac{1}{2\lambda_2} (\alpha + \alpha^*)^\top K_1 (\alpha + \alpha^*) + (\alpha - \alpha^*)^\top y \quad (32a)$$

$$\text{subject to} \quad \vec{1}^\top (\alpha - \alpha^*) = 0 \quad (32b)$$

$$\vec{1}^\top (\alpha + \alpha^*) = C m \nu \quad (32c)$$

$$0 \leq \alpha_i, \alpha_i^* \leq 1 \text{ for all } 1 \leq i \leq m \quad (32d)$$

Here  $K_1, K_2$  are kernel matrices where  $[K_i]_{jl} = k_i(x_j, x_l)$  and  $\vec{1}$  denotes the vector of ones. Moreover, we have the usual kernel expansion, this time for the regression  $f(x)$  and the margin  $\epsilon(x)$  via

$$f(x) = \sum_{i=1}^m (\alpha_i - \alpha_i^*) k_1(x_i, x) + b \text{ and } \epsilon(x) = \sum_{i=1}^m (\alpha_i + \alpha_i^*) k_2(x_i, x) + \epsilon. \quad (33)$$

The scalars  $b$  and  $\epsilon$  can be computed conveniently as dual variables of (32) when solving the problem with an interior point code.

### A.2 The $\nu$ -Property

As in the parametric case also (31) has the  $\nu$ -property. However, it is worth noting that the solution  $\epsilon(x)$  need not be positive throughout unless we change the optimization problem slightly by imposing a nonnegativity constraint on  $\epsilon$ . The following theorem makes this reasoning more precise:

**Theorem 8** *The minimizer of (31) satisfies*

1. *The fraction of points for which  $|y_i - f(x_i)| < \epsilon(x_i)$  is bounded by  $1 - \nu$ .*
2. *The fraction of constraints (31b) and (31c) with  $\xi_i > 0$  or  $\xi_i^* > 0$  is bounded from above by  $\nu$ .*
3. *If  $(x, y)$  is drawn iid from a distribution  $\Pr(x, y)$ , with  $\Pr(y|x)$  continuous and the expectation of the modulus of absolute continuity of its density satisfying  $\lim_{\delta \rightarrow 0} \mathbf{E}[\epsilon(\delta)] = 0$ . With probability 1, asymptotically, the fraction of points satisfying  $|y_i - f(x_i)| = \epsilon(x_i)$  converges to 0.*

*Moreover, imposing  $\epsilon \geq 0$  is equivalent to relaxing (32c) to  $\bar{\mathbf{I}}^\top(\alpha - \alpha^*) \leq C m \nu$ . If in addition  $K_2$  has only nonnegative entries then also  $\epsilon(x) \geq 0$  for all  $x_i$ .*

**Proof** The proof is essentially identical to that of Lemma 3 and that of Schölkopf et al. (2000). However note that the flexibility in  $\epsilon$  and potential  $\epsilon(x) < 0$  lead to additional complications. However, if both  $f$  and  $\epsilon(x)$  have well behaved entropy numbers, then also  $f \pm \epsilon$  are well behaved.

To see the last set of claims note that the constraint  $\bar{\mathbf{I}}^\top(\alpha - \alpha^*) \leq C m \nu$  is obtained again directly from dualization via the condition  $\epsilon \geq 0$ . Since  $\alpha_i, \alpha_i^* \geq 0$  for all  $i$  it follows that  $\epsilon(x)$  contains only nonnegative coefficients, which proves the last part of the claim. ■

Note that in principle we could enforce  $\epsilon(x_i) \geq 0$  for all  $x_i$ . This way, however, we would lose the  $\nu$ -property and add even more complication to the optimization problem. A third set of Lagrange multipliers would have to be added to the optimization problem.

### A.3 An Example

The above derivation begs the question why one should not use (32) instead of (6) for the purpose of quantile regression. After all, both estimators yield an estimate for the upper and lower quantiles.

Firstly, the combined approach is numerically more costly as it requires optimization over twice the number of parameters, albeit at the distinct advantage of a sparse solution, whereas (6) always leads to a dense solution.

The key difference, however, is that (32) is prone to producing estimates where the margin  $\epsilon(x) < 0$ . While such a solution is clearly unreasonable, it occurs whenever the margin is rather small and the overall tradeoff of simple  $f$  vs. simple  $\epsilon$  yields an advantage by keeping  $f$  simple. With enough data this effect vanishes, however, it occurs quite frequently, even with supposedly distant quantiles, as can be seen in Figure 9.

In addition, the latter suffers from the assumption that the error be symmetrically distributed. In other words, if we are just interested in obtaining the 0.95 quantile estimate we end up estimating the 0.05 quantile on the way. In addition to that, we make the assumption that the additive noise is symmetric.

We produced this derivation and experiments mainly to make the point that the adaptive margin approach of Schölkopf et al. (2000) is insufficient to address the problems posed by quantile regression. We found empirically that it is much easier to adjust QR instead of the symmetric variant.

In summary, the symmetric approach is probably useful only for parametric estimates where the number of parameters is small and where the expansion coefficients ensure that  $\epsilon(x) \geq 0$  for all  $x$ .

## Appendix B. Experimental Results

Here we assemble six tables to display the results across the four models. The first three tables report the pinball loss for each data set and the standard deviation across the 10 test runs. A lower figure is preferred

## NONPARAMTERIC QUANTILE ESTIMATION

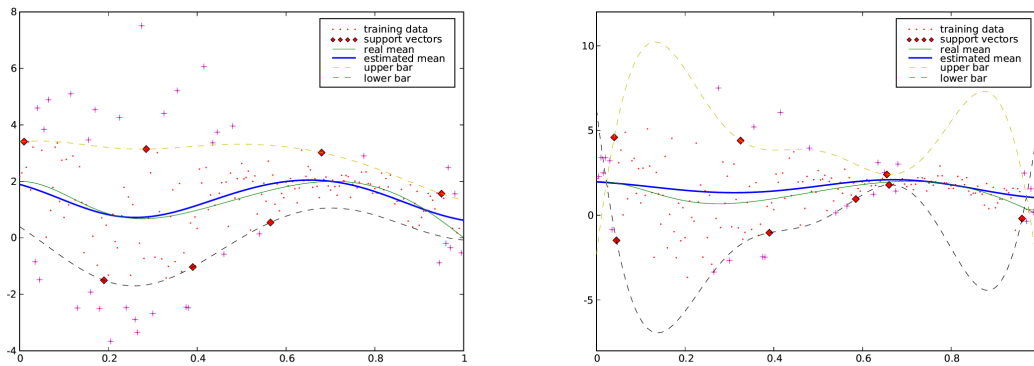

Figure 9: Illustration of the heteroscedastic SVM regression on toy dataset. On the left,  $\lambda_1 = 1$ ,  $\lambda_2 = 10$  and  $\nu = 0.2$ , the algorithm successfully regresses the data. On the right,  $\lambda_1 = 1$ ,  $\lambda_2 = 0.1$  and  $\nu = 0.2$ , the algorithm fails to regress the data as  $\epsilon$  becomes negative.

in each case. NA denotes cases where rqss Koenker (2005) was unable to produce estimates, due to its construction of the function system.

In the next three tables we measure the ramp loss. In each table a figure close the the intended quantile (10, 50 or 90) is preferred. For further discussion see the Results section of the paper.

Table 8: Comparison between the quantile regression without (npqr) and with (npqrm) monotonicity constraints. We tested on the cars and the onions dataset for monotonicity with respect to engine size and diameter respectively. Note that on the engines dataset the monotonicity constraint is not perfectly satisfied, as is manifest in the somewhat worse performance of npqrm, whereas for the onions yield estimation performance is improved when imposing monotonicity constraints.
